fragments can be sent in a row, as shown in Fig. 4-28. sequence of fragments is called a **fragment burst**.

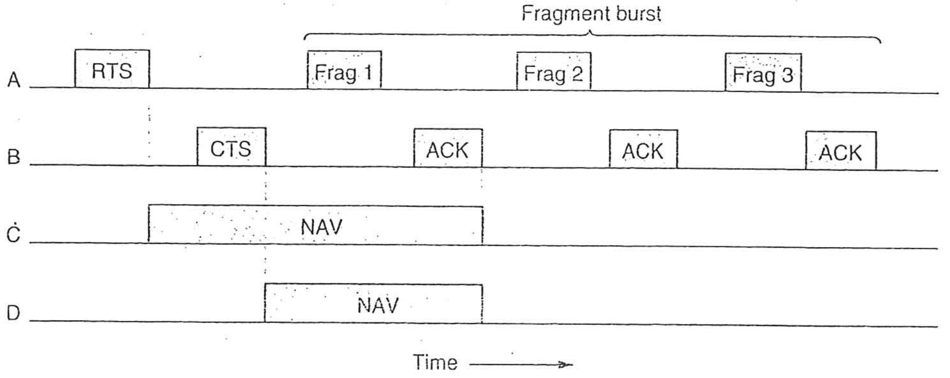

Figure 4-28. A fragment burst.

Fragmentation increases the throughput by restricting retransmissions to the bad fragments rather than the entire frame. The fragment size is not fixed by the standard but is a parameter of each cell and can be adjusted by the base station. The NAV mechanism keeps other stations quiet only until the next acknowledgement, but another mechanism (described below) is used to allow a whole fragment burst to be sent without interference.

All of the above discussion applies to the 802.11 DCF mode. In this mode, there is no central control, and stations compete for air time, just as they do with Ethernet. The other allowed mode is PCF, in which the base station polls the other stations, asking them if they have any frames to send. Since transmission order is completely controlled by the base station in PCF mode, no collisions ever occur. The standard prescribes the mechanism for polling, but not the polling frequency, polling order, or even whether all stations need to get equal service.

The basic mechanism is for the base station to broadcast a **beacon frame** periodically (10 to 100 times per second). The beacon frame contains system parameters, such as hopping sequences and dwell times (for FHSS), clock synchronization, etc. It also invites new stations to sign up for polling service. Once a station has signed up for polling service at a certain rate, it is effectively guaranteed a certain fraction of the bandwidth, thus making it possible to give quality-of-service guarantees.

Battery life is always an issue with mobile wireless devices, so 802.11 pays attention to the issue of power management. In particular, the base station can direct a mobile station to go into sleep state until explicitly awakened by the base station or the user. Having told a station to go to sleep, however, means that the base station has the responsibility for buffering any frames directed at it while the mobile station is asleep. These can be collected later.

PCF and DCF can coexist within one cell. At first it might seem impossible to have central control and distributed control operating at the same time, but

802.11 provides a way to achieve this goal. It works by carefully defining the interframe time interval. After a frame has been sent, a certain amount of dead time is required before any station may send a frame. Four different intervals are defined, each for a specific purpose. The four intervals are depicted in Fig. 4-29.

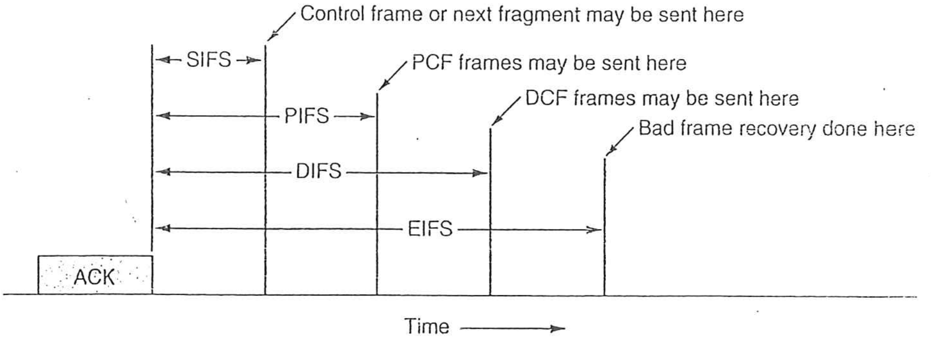

Figure 4-29. Interframe spacing in 802.11

The shortest interval is **SIFS (Short InterFrame Spacing)**. It is used to allow the parties in a single dialog the chance to go first. This includes letting the receiver send a CTS to respond to an RTS, letting the receiver send an ACK for a fragment or full data frame, and letting the sender of a fragment burst transmit the next fragment without having to send an RTS again.

There is always exactly one station that is entitled to respond after a SIFS interval. If it fails to make use of its chance and a time **PIFS (PCF InterFrame Spacing)** elapses, the base station may send a beacon frame or poll frame. This mechanism allows a station sending a data frame or fragment sequence to finish its frame without anyone else getting in the way, but gives the base station a chance to grab the channel when the previous sender is done without having to compete with eager users.

If the base station has nothing to say and a time **DIFS (DCF InterFrame Spacing)** elapses, any station may attempt to acquire the channel to send a new frame. The usual contention rules apply, and binary exponential backoff may be needed if a collision occurs.

The last time interval, **EIFS (Extended InterFrame Spacing)**, is used only by a station that has just received a bad or unknown frame to report the bad frame. The idea of giving this event the lowest priority is that since the receiver may have no idea of what is going on, it should wait a substantial time to avoid interfering with an ongoing dialog between two stations.

4.4.4 The 802.11 Frame Structure

The 802.11 standard defines three different classes of frames on the wire: data, control, and management. Each of these has a header with a variety of fields used within the MAC sublayer. In addition, there are some headers used by the
